Abstract: Reducing the acquisition time is important for clinical magnetic resonance imaging (MRI). Compressed sensing has recently emerged as a theoretical foundation for the reconstruction of magnetic resonance (MR) images from undersampled k-space measurements, assuming those images are sparse in a certain transform domain. However, most real-world signals are compressible rather than exactly sparse. For example, the commonly used 2D wavelet for compressed sensing MRI (CS-MRI) does not sparsely represent curves and edges. In this paper, we introduce a geometric image transform, the contourlet, to overcome this shortage. In addition, the improved redundancy provided by the contourlet can successfully suppress the pseudo-Gibbs phenomenon, a tiresome artifact produced by undersampling of k-space, around the singularities of images. For numerical calculation, a simple but effective iterative thresholding algorithm is employed to solve $l_1$ norm optimization for CS-MRI. Considering the recovered information and image features, we introduce three objective criteria, which are the peak signal-to-noise ratio (PSNR), mutual information (MI) and transferred edge information (TEI), to evaluate the performance of different image transforms. Simulation results demonstrate that contourlet-based CS-MRI can better reconstruct the curves and edges than traditional wavelet-based methods, especially at low k-space sampling rate.

1. Introduction

Undersampling k-space is a good way to speed up magnetic resonance imaging (MRI). However, undersampling often violates the Nyquist sampling rule, resulting in artifacts in reconstructed magnetic resonance (MR) images. Consequently, improving the resolution and suppressing artifacts are interesting and significant topics in undersampled MRI.

Up to now, undersampled MRI methods can be roughly classified into two categories, which exploit the redundancy in either k-space (e.g. using partial-Fourier [1] or following non-Cartesian trajectories to sample k-space [2-4]) or in the time domain. The latter is mainly focused on three dimensional MRI movies. These two types of methods are often used jointly, as the case of k-t sense [5,6].

MRI maps the spatial information, e.g. spin density, into the called k-space measurements with a finite Fourier integral, and the image is most commonly reconstructed by applying the inverse Fourier transform on these measurements. So, MR image reconstruction is linear because of the linearity of Fourier transform. However, the reconstruction is considered to be an ill-posed problem because one can not get a unique solution owing to finite sampling on a practical MRI scanner. When undersampling is applied, there exists more than one solution which fits the limited k-space measurements. This also enhances the uncertainty of finding the exact image. However, an appropriate image can be obtained with a known deviation from true image function [7]. A traditional and fruitful way for reconstructing undersampled MR images is to constrain reconstruction by including various prior information of images. A comprehensive review could be found in literature [8].
The emergence of compressed sensing (CS) theory [9,10] excites great interest in signal processing, optimization, inverse problems and medical imaging. The theory provides a foundation to reconstruct signals from measurements fewer than what is specified by Nyquist sampling rule with little or no information loss. Therefore, it is natural to introduce CS into undersampled MRI. Considering the specific requirements of MRI, CS has been applied to MRI with impressive reconstruction results in a few specific areas, e.g. 2D MRI [11-13], dynamic MRI [14] and so on [15,16]. In this paper, we call these sampling and reconstruction methods CS-MRI for short.

According to the CS theory, two key points need further investigation for undersampled MRI with high quality of reconstructed images and much fewer k-space measurements, which are:

(a) Coherence. CS requires the sampling matrix $\Phi$ to be incoherent with the basis dictionary $\Psi$ which sparsely represents MR image. The lower the coherence is, the less k-space measurements one needs. For MRI, $\Phi$ is directly determined by the encoding scheme. For example, non-Fourier encoding is applied to reduce the coherence [15]. Parallel MRI is also evidenced with lower coherence than traditional imaging schemes [16]. However, reducing coherence in traditional Fourier encoding is still an open problem.

(b) Sparsity. The number of measurements required for exactly recovering signals is proportional to $K$, the number of non-zero entries for a signal $x \in \mathbb{C}^N$, with respect to $\Psi$. The required k-space measurements will be very few if $\Psi$ can represent MR images sparsely. In CS-MRI, total variation (TV) [3,4,13] and wavelets [11,17] are commonly used as sparse transforms. TV penalizes local variation in the reconstructed image, while the wavelet transform
enforces point singularities and isotropic features. Both of them can greatly suppress the artifacts generated by undersampling the k-space.

Most real-world signals are not exactly sparse in any orthogonal basis, however, most common signals are compressible [18,19]. For example, the MR images of brains often contain curves and edges. TV and wavelet may fail in recovering some of these features. TV penalizes oscillation of texture, thus resulting in loss of texture [17,20]. 2D wavelet fails in recovering these features from a small number of measurements due to the shorthand in representing curves and edges [21,22]. Therefore, it is desirable to employ more effective sparse transform considering specific image features for CS-MRI.

In recent years, some geometric image transforms have been proposed for sparse image representation. In this paper, focusing on recovering the curves and edges, we introduce one of these transforms, namely the contourlet transform [22], into CS-MRI. To further improve the sparsity, we increase the redundancy of the contourlet transform. One reason that we turn to redundant representation is the desire to have the shift variance property [23]. This property can overcome the pseudo-Gibbs phenomenon around singularities, e.g. blurring in edges, thus improving the image quality of undersampled MR images [24]. For numerical computation of reconstruction, a simple but effective iterative thresholding algorithm, which has not been used in CS-MRI before, is employed in this paper. We analyze the convergence of iterative thresholding by introducing objective criteria to evaluate the performance of CS reconstruction.

In the rest of this paper, a brief introduction of CS-MRI is given in Section 2. The theoretical foundation of contourlet-based CS-MRI and the iterative thresholding algorithm is presented in Section 3. In Section 4, objective criteria and simulation results are discussed. Finally, the
conclusion is given in Section 5.

2. Compressed sensing for MRI

The Compressed sensing (CS) proposed by Candès et al. [9] and Donoho [10] is a new sampling and compression theory. Its main idea is that a signal can be exactly or approximately recovered from highly incomplete measurements if the signal is sparse in a certain domain.

Suppose that signal $x \in \mathbb{C}^N$ is sampled by a sensing matrix $\Phi_{M \times N}$, then the measurements $y \in \mathbb{C}^M$ of $x$ are

$$y_{M \times 1} = \Phi_{M \times N} x_{N \times 1}.$$  

If $M < N$, it seems hard to recover $x$ by solving the underdetermined system of equations. According to the CS theory, under the assumption that $x$ can be sparsely represented in transform $\Psi$ domain and $\alpha$ is the coefficient with respect to $\Psi$, $x$ can be presented as

$$x = \Psi \alpha$$

The sparsity is often expressed as

$$\|\alpha\|_0 = \|\Psi^* x\|_0 \ll N$$

where $\|\alpha\|_0$ denotes the $l_0$ quasi-norm and is defined as $\|\alpha\|_0 = \# \{ \alpha_i \neq 0, i = 1, 2, \cdots, I \}$ which counts the nonzero entries in $\alpha$ with the length $I$. $\Psi$ and $\Psi^*$ mean the inverse and forward sparse transforms, respectively.

CS tries to reconstruct the signal from undersampled measurements by minimizing $l_0$ norm optimization. Letting $\hat{\alpha}$ denote the estimation of $\alpha$, the $l_0$ norm optimization is

$$\hat{\alpha} = \min_{\alpha} \|\alpha\|_0, \text{ s.t. } y = \Phi \Psi \alpha$$

However, the $l_0$ norm is known to be intractable and sensitive to noise [9,10], so $l_1$ norm
convex optimization is commonly used in CS to recover \( \hat{x} \)

\[
\hat{x} = \min_{\alpha} \|\alpha\|_1, \quad s.t. \quad y = \Phi \Psi \alpha
\]  

(1)

where \( \|\alpha\|_1 \) denotes the \( l_1 \) norm, i.e. the sum of absolute values of vector elements \( \alpha_i (i = 1, 2, \cdots, I) \), and is defined as \( \|\alpha\| = \sum_{i=1}^{I} |\alpha_i| \). The recovered signal \( \hat{x} \) is equal to \( \Psi \alpha \).

For MRI, continuous spatial information \( x(r) \), e.g. spin density, is often represented as the sum of \( N \) voxels in a discretized form \([7,15]\)

\[
x(r) = \sum_{n=1}^{N} x_n \phi(r - r_n)
\]

where \( \phi(r) \) is the voxel basis function (typical choices include Dirac and box functions) and the \( r_n \) vectors specify the voxel grid. Therefore, the vector form of \( x(r) \) can be expressed as

\[
x_{N \times 1} = \left[ x_1, x_2, \cdots, x_n, \cdots, x_N \right]^T
\]

Then the spatial information is then mapped into the so called k-space measurements \( y(k) \) with a finite Fourier integral as

\[
y(k) = \int_{\mathbb{R}^2} x(r) e^{-j2\pi k^T r} \, dr = \int_{\mathbb{R}^2} \sum_{n=1}^{N} x_n \phi(r - r_n) e^{-j2\pi k^T r} \, dr, m = 1, 2, \cdots, M
\]

(2)

where the integration is performed on the plane \( \mathbb{R}^2 \) for the two dimensional MR image and \( y(k_m) \) is the value at the \( m \)th k-space location \( k_m \). Thus, \( y(k) \) can be expressed as the vector as

\[
y_{M \times 1} = [y(k_1), y(k_2), \cdots, y(k_m), \cdots, y(k_M)]^T
\]

If the \( M \times N \) encoding matrix \( \Phi \) is defined as

\[
\Phi_{m,n} = \int \phi(r - r_n) e^{-j2\pi k^T r} \, dr
\]

then Equation (2) can be written in matrix form as

\[
y_{M \times 1} = \Phi_{M \times N} x_{N \times 1}
\]

(3)

where \( y = [y_1, y_2, \cdots, y_M]^T \) is the data vector \( y \in \mathbb{C}^M \) and \( x = [x_1, x_2, \cdots, x_N]^T \) is the vector of voxel coefficients \( x \in \mathbb{C}^N \).
For CS-MRI, the encoding matrix $\Phi$ is denoted as the undersampled Fourier transform operator $F_u$ to avoid the ambiguity expression with other applications of CS. $F_u$ directly relies on the sampling scheme. $M < N$ means that the acquired k-space samples is incomplete, therefore there exists more than one solution to fit for Equation (3).

According to Equation (1), the reconstructed MR image is estimated by solving the constrained optimization problem under the assumption that $x$ can be sparsely represented in transform $\Psi$ domain,

$$\hat{a} = \min_a \|a\|, \quad s.t. \quad y = F_u \Psi a$$

(4)

The reconstructed MR image is $\hat{x} = \Psi \hat{a}$. Since $y$ is a complex vector, $\hat{a}$ and $\hat{x}$ are complex too. However, since $y$ is often contaminated by noise, one needs to estimate the minimal $\|a\|$ by solving the equation

$$\hat{a} = \min_a \|a\|, \quad s.t. \quad \|y - F_u \Psi a\|_2 < \varepsilon$$

(5)

The notation $\|\cdot\|_2$ stands for $L_2$ norm defined as $\|m\|_2 = \left(\sum_{i=1}^{I} |m_i|^2 \right)^{\frac{1}{2}}$ where $I$ is the total number of elements of $m$. $\varepsilon$ controls the fidelity of the reconstruction to the measured k-space samples. The solution $\hat{a}$ has a small $L_1$ norm to enforce the sparsity and fits the data up to a tolerance $\varepsilon$.

Ingrid et al [25] proved that generalizing Tikhonov’s regularization method from the $L_2$ norm penalty case to the $L_1$ norm penalty provides a proper regularization method for an ill-posed problem $y = \Phi x$ as

$$\hat{a} = \min_a \|y - \Phi \Psi a\|_2^2 + \sum_{i=1}^{I} \omega_i |\alpha_i|^p$$

(6)

where $\alpha_i$ is the $i^{th}$ element of vector $a$ with length $I$ in orthonormal basis $\Psi$, e.g.
wavelet basis. $\omega_i$ is the weight for $\alpha_i$. The notation $|\alpha_i|^p$ stands for $p$th power of the absolute value of $\alpha_i$.

For the special case when $p = 2$ and $\omega_i$ is some positive constant $\omega_i = \beta$, Equation (6) reduces to the standard Tikhonov regularization equation

$$\hat{\alpha} = \min_{\alpha} \| y - \Phi \Psi \alpha \|^2_2 + \beta \sum_{i=1}^{l} |\alpha_i|^2$$

(7)

where $\beta$ gives the trade off between the data fidelity and $l_2$ norm of vector $\alpha$.

Compared with the standard Tikhonov regularization in Equation (7), the generalized Tikhonov regularization in Equation (6) puts a lesser penalty on only a few large entries of $\alpha$, and a higher penalty on many small entries of $\alpha$. Thus, the second term in Equation (6) promotes sparsity of the expansion of $x = \Psi \alpha$ with respect to the orthonormal basis $\Psi$. For the special case $p = 1$, the generalized Tikhonov regularization becomes the unconstrained form of $l_1$ norm optimization in compressed sensing [11].

3. Iterative thresholding CS-MRI based on contourlet transform

3.1 Compressible CS-MRI

Compressed sensing works well when the signal is exactly sparse. Suppose an ideal MR image (or MR image reconstructed from fully sampled k-space) is $\tilde{x} \in \mathbb{C}^N$, CS could work efficiently if the MR image is sparse with respect to the forward transform $\Psi'$, which means

$$\|\Psi' \tilde{x}\|_0 \ll N$$

However, most real-world signals are not exactly sparse in any orthogonal basis but compressible [18,19]. As a widely used image sparsifying transform, the wavelet transform has great success in representing point singularities, including for CS-MRI [11,18]. Unfortunately, the traditional 2D wavelet is a tensor-product of the 1D wavelet. It is a separable extension from the 1D basis.
Thus, it is not good at representing curves [21,22]. The representation of curves by the 2D wavelet is just compressible, i.e. satisfying the power law decay if the image is constructed from the $k$ largest magnitude coefficients in the wavelet domain.

The contourlet transform was recently pioneered by Do and Vetterli [22]. Compared with the wavelet transform, it provides a flexible rather than fixed number of directions at each scale and thus can capture the intrinsic geometrical structure of images. Unlike the curvelet [21], which is another geometric image transform initially developed in continuous domain and then discretized for sampled data, the contourlet is constructed directly in a discrete domain and enjoys low computing complexity. It requires $O(N)$ operations for $N$-pixel images [22]. Thus, the contourlet can be easily implemented for MR images. Furthermore, the iterated filter banks algorithm in the contourlet transform allows one to choose different filters to represent the features of MR image. We adopt a sharp frequency localization contourlet (SFLCT) [26] that outperforms the original contourlet [22]. The new contourlet successfully cancels the aliasing components outside the desired trapezoid-shaped support. As is shown in Figure 1, it employs a new multiscale pyramid with different sets of lowpass and highpass filters for different levels.

In contrast with the nonsubsampled contourlet [27] to obtain fully shift-invariant property at the price of large time consumption, SFLCT is a semi-redundant contourlet transform. It only increases the redundancy in the lowpass filter because the pseudo-Gibbs phenomenon of original contourlet [22] is mainly induced by downsampling in the lowpass filter $L_0(\omega)$ [26,27]. Lu et al designed the lowpass filter $L_0(\omega)$ to cancel aliasing component in images. The 1D forms of $L_0(\omega)$ and $L_4(\omega)$ [26] is
Inverse Problems in Science and Engineering

\[
L_i(\omega) = \begin{cases} 
1 & \text{for } |w| \leq w_{p,i} \\
\frac{1}{2} + \frac{1}{2} \cos \left( \frac{|w| - w_{p,i}}{w_{s,i} - w_{p,i}} \pi \right) & \text{for } w_{p,i} \leq |w| \leq w_{s,i} \\
0 & \text{for } w_{s,i} \leq |w| \leq \pi 
\end{cases}
\]

where $|\omega| \leq \pi$, $i = 0, 1$, $w_{p,i}$ is the passband frequency and $w_{s,i}$ is the stopband frequency.

In addition, the iterative decomposition structure of SFLCT, shown in Figure 1, provides us an opportunity to easily handle the redundancy of the contourlet. For example, if we do not downsample the lowpass filter $L_0(\omega)$, the redundancy of contourlet is 2.33. If we downsample the lowpass filter $L_0(\omega)$ by setting $\downarrow (d, d) = \downarrow (2, 2)$ where $d$ is the downsampling parameter that determines the redundancy of contourlet, the redundancy of the contourlet is 1.33 [26]. Consequently, SFLCT is a good choice for practical CS-MRI to easily control the redundancy and reduce the computing complexity. For simplicity, the contourlet mentioned in the rest of this paper refer to SFLCT.

Figure 2 shows the basis elements of wavelets and contourlets. The wavelet basis has only three directions while the contourlet basis is anisotropic and has arbitrary directions (commonly $2^m$ ($m \leq 5$)). Equipped with these bases, the contourlet requires fewer coefficients to represent curves of MR images than the wavelet does.

For a 2D piece-wise smooth image $x$ with twice continuously differentiable discontinuities (called $C^2$ singularities) [29], if we keep the $k$ largest magnitude terms in the bases, the optimal approximation rate of the contourlet [22] achieves
\[
\|x - \hat{x}_k\|_2 \propto O\left(k^{-2}\right)
\]

For wavelets, the error decay rate [21,22] is
\[
\|x - \hat{x}_k\|_2 \propto O\left(k^{-1}\right)
\]
According to the CS theory, if we make the number of measurements \( M \geq \text{Const} \cdot k \cdot \log N \) for a compressible signal \( x \in \mathbb{C}^N \), the solution \( \hat{x} \) to Equation (4) has the same error decay as does \( \hat{x}_k \) [28]

\[
\|x - \hat{x}_M\|_2 \propto O(k^{-r})
\]

which means that the reconstruction error is proportional to the power law decay \( k^{-r} \). By using the contourlet as the sparse transform for an object with \( C^2 \) singularities, the reconstruction error \( (k^{-2}) \) attenuates faster than that of wavelets \( (k^{-1}) \) when \( k > 1 \). It implies that when an image contains more curves, the reconstruction error of the contourlet is lower than that of the wavelet from undersampled k-space. That is why we use the contourlet as the geometric transforms in this paper.

Aiming to recover the curves with less error and to control the redundancy of transforms easily, we select the SFLCT as the sparse transform for CS-MRI in this paper.

### 3.2 Numerical calculation

Many scientists seek for simple and fast algorithms to solve Equation (1), such as the conjugate gradient method [11], Bregman iteration [17], the interior point method [30] and other methods. However, these methods are not straightforward in solving the problem of constraint \( l_1 \) norm optimization of CS [11,30]. In this paper, we employ iterative thresholding [25, 31-36], a simple but effective algorithm, which has never been reported in CS-MRI to solve Equation (5). The iterative thresholding algorithm directly cancels the interference caused by undersampling the k-space [11], and has been recommended to solve CS problems [34].

The classic interpretations of iterative thresholding for solving constraint \( l_1 \) norm
optimization were reported previously [25,32]. For theoretic analysis, Herrity et al employed hard iterative thresholding to demonstrate that one could recover the k-term representation of the original signal up to any prescribed error tolerance under certain conditions [33]. Their simulation results showed that soft iterative thresholding performed better than hard thresholding. Bredies and Lorenz proved that soft iterative thresholding converged with a linear rate once the underlying operator satisfied the finite basis infectivity property or the minimizer possessed a strict sparsity pattern [31]. In addition, only two free parameters, which are independent of transforms, must be set in iterative thresholding algorithm. It allows convenient comparison among different transforms.

Inspired by the work of those authors and the convenience of iterative thresholding, we apply soft iterative thresholding to solve CS-MRI. It is defined as follows:

\[
S_\theta(\alpha_i) = \begin{cases} 
\alpha_i + \theta & \alpha_i \leq -\theta \\
0 & |\alpha_i| < \theta \\
\alpha_i - \theta & \alpha_i \geq \theta 
\end{cases}
\]  

(9)

where \(\alpha_i (i = 1, 2, \ldots, I)\) is the \(i^{th}\) entry in \(\alpha\). Since \(\alpha\) is a complex vector for MR images, we use the complex thresholding operator defined as \(S_\theta(\{|\alpha_i|e^{j\omega}\}) = S_\theta(\{|\alpha_i|\})e^{j\omega}\). For simplicity, let \(S_\theta(\alpha)\) denotes the soft thresholding operation that performs on all the entries of \(\alpha\) with the same threshold \(\theta\) according to Equation (9).

Different from the sparsity constraint denoising problem presented in [32], we aim at reconstructing MR images from undersampled k-space, so we need to modify the iterative thresholding algorithm. For simplicity, we use \(A\) to stand for \(F_u\Psi\) and \(A^* = \Psi^*F_u^*\) denotes the adjoint transpose of \(A\). Because the contourlet is established by frame theory, \(\Psi^*\) means the forward contourlet transform, while \(\Psi^\dagger\) means the inverse transform for CS [36].
The soft iterative thresholding algorithm for CS-MRI can be implemented according to the following steps:

Step 1: Initialization. The coefficients vector \( \alpha_0 = [0, 0, \cdots, 0]^T \), the reconstructed image \( x_0 = \Psi \alpha_0 \), the residual \( r_0 = y \), and the initial threshold \( \theta_0 = \max(A^* r_0) \) where \( A^* = \Psi^* F_u^* \) denotes the adjoint transpose of \( A \). The notation \( F_u^* \) means to do inverse Fourier transform on undersampled the Fourier coefficients \( r_0 \) while \( \Psi^* \) means the forward contourlet transform.

Step 2: Update the coefficients vector \( \alpha_{t+1} = \alpha_t + S_{\theta_t}(A^* r_t) \) by applying soft iterative thresholding according to Equation (9), and the residual \( r_{t+1} = y - A \alpha_{t+1} \). Decrease the threshold \( \theta_{t+1} = \rho \theta_t \), in which \( \rho \) is a decrease factor and typically defined as \( 0 < \rho < 1 \).

Step 3: Repeat Step 2 until the residual \( r \) satisfies the given stop criteria. Output the estimated coefficients \( \hat{\alpha} \) and the reconstructed image \( \hat{x} = \Psi \hat{\alpha} \).

Since the acquired k-space measurements are often contaminated by noise, the stop criteria of iterative thresholding for CS-MRI is directly related to \( \varepsilon \) of Equation (5). In order to eliminate the effect of the magnitude of MR images on stop criteria, we change the traditional absolute stop criteria into a relative form as

\[
\eta = \frac{||A \hat{\alpha} - y||_2}{||y||_2}
\]

(10)

Accordingly, relative residual \( R \) is defined in a relative form as

\[
R_t = \frac{||A \alpha_t - y||_2}{||y||_2}
\]

(11)

Suppose that at the \( t^{th} \) iterative time, the final estimated coefficient \( \hat{\alpha} = \alpha_t \), if \( R_t \leq \eta \).

With the same meaning as \( \varepsilon \) in compressed sensing in Equation (5), the stop criteria \( \eta \) is
set as large if the k-space is corrupted by heavy noise, while \( \eta \) is small for light noise. It is worth noting that estimating the noise contained in k-space is very significant. If \( \eta \) is smaller than the true noise level, more noise will be presented in the reconstructed image. On the other hand, if \( \eta \) is larger than the true noise level, image details will be lost since they are taken as noise and thrown away. More details will be discussed in subsection 4.2.3.

In the algorithm, \( \rho \) is adopted to decrease the threshold \( \theta_i \) in each iteration, typically defined as \( 0 < \rho < 1 \). The smaller \( \rho \) is, the faster \( \alpha \) comes to convergence.

The two parameters \( \eta \) and \( \rho \) presented in the algorithm are constants, and we set them to be the same in all simulations except when we discuss the convergence of soft iterative thresholding in subsection 4.2.3. From empirical analysis, \( \eta = 10^{-6} \) and \( \rho = 0.8 \) assure promising results.

Two factors affecting the computational complexity of the algorithm are iteration times and multiplications involving \( A \) and \( A^* \). For the former, no nested loop is involved in this algorithm, and sufficient tests show that the algorithm approaches the stop criteria after only tens of iterations. For the latter, only one multiplication by \( A \) and one by \( A^* \) are performed per iteration. Simulations in subsection 4.2.3 show that different transforms reach the stop criteria after a similar number of iterations, implying that the speeds of different transforms are mainly related to the computational complexity of their forward and inverse transforms.

4. Simulation results and analysis

4.1 Objective performance evaluation

Objective evaluation of performance of different methods is an important issue. Focusing on
the influence of sparse transforms on the curve features and the information of reconstructed images, besides the visual appearance, we introduce three objective criteria to evaluate the correlation between reconstructed MR images from fully sampled and undersampled k-space. They are the peak signal-to-noise ratio (PSNR), mutual information (MI) [37] and transferred edge information (TEI) [38].

Suppose $\tilde{x}$ is the fully sampled k-space MR image, $\hat{x}$ is the solution of Equation (5) and the gray value of $\hat{x}$ is 0 to 255.

PSNR is defined as

$$PSNR = 20 \log_{10} \left( \frac{255}{\sqrt{MSE}} \right)$$

where

$$MSE = \frac{1}{M \times N} \sum_{i=0}^{M-1} \sum_{j=0}^{N-1} (\tilde{x}(i,j) - \hat{x}(i,j))^2.$$ 

MI is defined as

$$MI = \sum p(\tilde{x}, \hat{x}) \log \frac{p(\tilde{x}, \hat{x})}{p(\tilde{x})p(\hat{x})}$$

where $p(\tilde{x}, \hat{x})$ is the joint probability distribution and $p(\bullet)$ is the marginal probability distribution.

TEI is defined as

$$TEI = Q_g^{\tilde{x}} Q_\alpha^{\hat{x}}$$

where $Q_g^{\tilde{x}}$ and $Q_\alpha^{\hat{x}}$ [38] stand for the edge strength and orientation preservation values.

PSNR evaluates the difference between the gray values of fully sampled k-space MR image and CS-based reconstructed image. MI essentially computes how much information from fully sampled k-space MR image is transferred to CS-based reconstructed image. TEI measures the amount of edge information that CS reconstructs using a Sobel edge detector which computes the
horizontal derivative approximation $G_x$ and vertical derivative approximation $G_y$ with a two
dimensional convolution operation on image $f$ as follows:

$$G_x = \begin{bmatrix} 1 & 0 & -1 \\ 2 & 0 & -2 \\ 1 & 0 & -1 \end{bmatrix} * f$$

and

$$G_y = \begin{bmatrix} 1 & 2 & 1 \\ 0 & 0 & 0 \\ -1 & -2 & -1 \end{bmatrix} * f$$

4.2 Simulation results

In the simulation, we use a binary mask with equal size of k-space to determine which k-space
measurements are acquired. If the value of mask at location $(x, y)$ is equal to 1, the
measurement at location $(x, y)$ is acquired. The ratio of k-space measurements acquired in
undersampling, named as sampling rate, is between 0 and 1. We call the binary mask the sampling
pattern because it directly determines the way to sample the k-space.

To demonstrate the performance of the contourlet transform and the efficiency of soft
iterative thresholding, first we will show the weakness of traditional 2D wavelet on representing
curves in CS-MRI. This shortcoming can be successfully overcome by contourlets. The
pseudo-Gibbs phenomenon around edges can be suppressed as well by improving the redundancy
of the contourlet. We will then show the objective criteria at different sampling rates with two
sampling patterns. Finally, the convergence of soft iterative thresholding will be presented.

We use Daubechies wavelet with 4 vanishing moments and 4 decomposition levels. SFLCT is
with decomposition level $[5,4,4,3]$, which means 4 decomposition levels and $2^5, 2^4, 2^4, 2^3$
directional subbands from coarse to fine scales. One type of quincunx/fan filters named pkva [39],
which can effectively localize edge direction [40], is employed as a decomposition filter in SFLCT.
The non-redundant contourlet downsamples the first lowpass filter with factor 2, while the
redundant contourlet does not downsample first lowpass filter. Both forms of contourlets use critical downsampled directional filter banks.

4.2.1 Overcoming the shortage of the wavelet transform

In this subsection, parameters of iterative thresholding are $\varepsilon = 10^{-4}$, $\eta = 10^{-6}$ and $\rho = 0.8$.

Figure 3(a) is the Cartesian sampling pattern for reducing the phase encoding time. The k-space data are acquired at the locations of white pixels as shown in Figure 3(a) and the other k-space data are filled with zeros. The sampling rate is 0.36, which means only 36 percent of k-space is acquired.

Filling zeros into k-space produces curve-like artifacts in Figure 3(c). The Cartesian sampling pattern makes the artifacts, commonly evaluated by the point spread function [10,14], spread in the zero-filling image. Figures 3(d)-(f) show that CS can suppress these artifacts and obtain clearer images.

The zoom in parts in Figures 3(d) and (e) show that contourlet outperforms wavelet in reconstructing the curves of MR image. This conclusion is also demonstrated by the objective criteria in Table 1 which implies contourlet can obtain higher TEI than wavelet.

Just as in image denoising, thresholding coefficients of image transform would induce pseudo-Gibbs phenomenon around edges. Improving the redundancy of the transform is a good way to suppress these effects. Figures 3(e) and (f) indicate that redundant contourlets can suppress the artifacts better than non-redundant contourlets. The objective criteria in Table 1 also demonstrate this conclusion.
The aforementioned example shows that undersampling the k-space with Cartesian sampling pattern will introduce curve-like artifacts. These artifacts tend to be considered as meaningful image features, and cannot be sufficiently suppressed by CS. In the view of point spread function [11,15] for CS-MRI, a good sampling pattern should be able to make the artifacts look like random noise. From this aspect, the variable density sampling pattern, shown in Figure 4(a), works well in our empirical simulation. This pattern is also recommended in literature [41]. Figure 4(c) shows variable density sampling pattern makes the artifacts much like the noise. Though the sampling rate is half of that for Cartesian sampling pattern of Figure 3(a), the reconstructed images in Figures 4(d)-(f) are much better than those in Figures 3(d)-(f). The zoom in parts in Figures 4(d) and (e) show that contourlet can better preserve edge than wavelet. This conclusion is also demonstrated by the objective criteria in Table 2.

4.2.2 Contourlet-based CS at different sampling rate

In this subsection, we will show the performance of different transforms at different sampling rates. Parameters of iterative thresholding are \( \varepsilon = 10^{-4} \), \( \eta = 10^{-6} \) and \( \rho = 0.8 \).

Figure 5 shows the variations of the objective evaluation criteria of CS-MRI versus sampling rates for the wavelet and the contourlet in reconstructing the MR image in Figure 3(b). The curves in the left column of Figure 5 show the criteria when a Cartesian sampling pattern is applied for undersampling and the curves in the right column of Figure 5 show the criteria when a variable density sampling pattern is applied for undersampling.

All criteria indicate that the contourlet can better preserve edges and recover more information than the wavelet does, especially at low sampling rates. For example, compared with
wavelets, the non-redundant contourlet improves the TEI by 20% at the sampling rates of 0.4 and 0.2 with Cartesian sampling pattern. The advantage of contourlet holds true for both Cartesian and variable density sampling patterns.

Figure 5 also indicates that, with the increase of sampling rate, the superiority of contourlet becomes less obvious. For example, when the sampling rate of Cartesian pattern is above 0.8 or that of variable density sampling pattern is above 0.6, the criteria of contourlet and wavelet are nearly the same. According to the CS theory, if the sampling rate is sufficiently high and the transform can make the image sparse enough, the difference between transforms will only have slight effect on the reconstruction performance. However, most real-world signals are compressible but not sparse. The reconstruction error is proportional to the decay rate of $\kappa^{-r}$, as shown in Equation (8). For edges and curves, the contourlet has $r = 2$ while the wavelet has $r = 1$. This is the reason why we can better reconstruct the edges and curves using contourlet than using wavelet in CS-MRI. In addition, a high sampling rate is meaningless for practical MRI application since high sampling rate means the reduction of acquired data is insignificant. Therefore, it is worthy to seek for geometric image transforms to better reconstruct MR images from highly undersampled k-space. A good geometric image transform we pursuit should at least enjoy some advantage in recovering certain image features over the others.

The comparison between the curves in the left and right columns of Figure 5 indicates that higher criteria are achieved by variable density sampling pattern relative to Cartesian sampling pattern at the same sampling rate. The reason is that variable density sampling pattern makes the artifacts look like random noise. This implies that the sampling pattern plays an important role in further reducing the measurements in k-space.
4.2.3 Numerical convergence of iterative thresholding

First, we use the objective criteria PSNR, TEI and MI to show the convergence of iterative thresholding at different values of the stopping criterion $\eta$. Parameters of iterative thresholding are $\rho = 0.8$ and $\eta = 10^{-l}$ ($l = 1, 2, \ldots, 9$).

At the beginning, the relative noise level $\eta$ in Equation (10) is set as a constant of $10^{-6}$. We use the variable density sampling pattern with sampling rate 0.15 in Figure 6(a). The reconstructed image using the wavelet, the non-redundant contourlet and the redundant contourlet are shown in Figures 6(c)-(f). Figure 7(a) shows that with the increased iterations, the relative residual $R_t$ in Equation (7) of all the transforms reaches $\eta$. Though the image is compressible, not rigorously sparse in transform domain, iterative thresholding can recover the representation of fully-sampled image up to any prescribed error tolerance, which is consistent with the results for k-term sparse signals [33]. If the number of iterations increases, the relative residual $R_t$ will decrease, but the objective criteria, shown in Figures 7(b)-(d), tend to go stable and will eventually not increase.

Each transform comes to converge with almost the same speed, though the contourlet comes to $\eta$ slightly faster than the wavelet. Values of PSNR, TEI and MI in Figures 7(b)-(d) show that the redundant contourlet obtains the highest objective criteria after the initial few iterations. This also demonstrates that the redundant contourlet can give the best reconstructed image, shown in Figure 6(f), at low sampling rate in k-space measurements.

Given a different stop criterion $\eta$ of iterative thresholding, a large $\eta$ corresponds to a sampled k-space highly corrupted by noise, while a small $\eta$ corresponds to relatively low noise. Figure 8(d) shows that a too large $\eta$ makes the image too smooth and loses texture. $\eta \leq 10^{-6}$.
is sufficient to preserve image details and suppress the noise very well. Smaller $\eta$, e.g. $10^{-8}$ or $10^{-9}$, also suppress the noise well because the $l_1$ norm enforces the sparsity to recover image details and noise is not sparse in contourlet domain. However, a smaller $\eta$ requires more iterations. $\eta = 10^{-6}$ is empirically feasible. The objective criteria shown in Figures 9(a)-(c) prove that this conclusion holds since criteria do not improve with the decreasing of $\eta$ when $\eta \leq 10^{-6}$. It is obvious that estimating the noise in k-space is very significant for CS-MRI. A precise estimation of noise can suppress the noise and preserve image details very well.

Second, we investigate and report the numerical results with various values of $\rho$. The sampling pattern in Figure 6(a) and the MR image in Figure 6(b) are employed in simulation. $\eta$ is set as $\eta = 10^{-6}$. $\rho$ varies from 0.1 to 0.95. The $i^{th}$ value of $\rho$ is $\rho_i \in \{0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9\}$ ($i = 1, 2, \ldots, 10$).

Figures 10(a)-(c) show that increasing $\rho$ leads to higher objective criteria, which means an improvement on quality of reconstructed image. However, the improvement is at the expense of more iterations in reconstruction, as shown in Figure 10(d). This expense is serious, especially when $\rho > 0.8$. For example, the number of iterations, when $\rho = 0.9$, is nearly twice as that when $\rho = 0.8$. So, there is a tradeoff between number of iterations and objective criteria. Figure 10(e) shows the PSNR versus number of iterations. Each square point corresponds to one $\rho$ as shown in Figure 10(d). Figure 10(e) indicates that with the increase of $\rho$, the gain in image quality brought by increasing the iterations becomes slight when $\rho > 0.8$. This is also the case in TEI and MI because their similar relationship with $\rho$. So, $\rho = 0.8$ is a good choice regarding with both objective criteria and number of iterations. For the sake of very good criteria, $0.8 \leq \rho \leq 0.9$ is recommended.
5. Discussion and conclusions

In this paper, a geometric image transform, the contourlet, is introduced into CS-MRI and a simple but efficient iterative thresholding algorithm is applied to solve $l_1$ optimization of CS-MRI. Considering the transferred information and edge features, we introduce objective criteria to evaluate the performance of different geometric image transforms in CS-MRI. Simulation results demonstrate that enforcing the sparsity of the image in the contourlet transform domain can better reconstruct the curves of MR images than the traditional wavelet, especially at low sampling rates of k-space. Furthermore, improving the redundancy of the contourlet can better suppress the blurring artifact in reconstructed MR images. The convergence of iterative thresholding algorithm is analyzed in simulations.

However, most MR images are not sparse in one transform domain. This paper only presents how to better reconstruct the curves and edges by applying a geometric image transform. For further improvements in reconstructing MR images, combination of multiple transforms which sparsely represents different image structures, i.e. constructing redundant basis, is a wise choice for CS-MRI. This is one of our future works and the primary results were published in [42] in the mean time of revising this paper. Nevertheless, as an emergent sampling and reconstruction method for MRI, compressed sensing will have further applications to improve the imaging speed.

Acknowledgements

This work was partially supported by NNSF of China under Grants (10774125, 10875101, and 10605019). Xiaobo Qu and Di Guo would like to acknowledge the fellowship of Postgraduates’
Oversea Study Program For Building High-Level University from the China Scholarship Council.

The authors would like to thank Dr. M. Lustig for sharing the source code of compressed sensing MRI and Dr. Y. Lu for sharing the source code of sharp frequency localization contourlet. The authors also thank Miss X. Cao, Mr. Anthony Christodoulou and Mr. Diego Hernando for their great help in the preparation of the manuscript. The authors also thank the reviewers for their thorough review and highly appreciate the comments and suggestions, which significantly contributed to improving the quality of this paper.
